

CHAPTER 3

Potential Roles of Fragmented Forests on Succession in Pine Plantations

Abstract

The research was carried out at Boakaew Watershed Management Station, Chiang Mai province, in 2009. A plot, 40 x 40 m² in size, was used for vegetation sampling in each of fifteen fragmented forests remained in areas between 1,200-1,500 m altitude nearby pine plantations. Stem girth at breast height and height of all tree species were measured for calculating quantitative characteristics. Two plots, 5 x 5 m² in size, were used for studying natural regeneration. The forest type was lower montane forest. Species richness in whole fragmented forests was 103 tree species (82 genus and 44 families). Fagaceae was the most dominant family. The dominant trees in most fragmented forests were *Pinus kesiya* and *Castanopsis acuminatissima*, whereas some were dominated by *Schima wallichii* and *C. diversifolia*. Tree densities were greatly varied among the fragmented forests, 556-1,769 trees/ha with the total stem basal areas of 17.46-36.58 m²/ha. These implied to the variable forest conditions and plant community similarity among the forests. The forest varied from degraded to good forests. The Shannon-Wiener Index of species diversity was high, 5.28. Tree species in the families of Pinaceae, Juglandaceae and Bignoniaceae have seed dispersal by wind whereas those of heavy seeds are belong to Fagaceae, Lauraceae and Proteaceae which have seed dispersal by gravity force and animal. Differences in seed/fruit morphology are related to the their dispersal and spatial distribution of tree species, and have the high potential roles on plant succession in surrounding pine plantations.

3.1 Introduction

The tropical forest biome of Southeast Asia has been recognized as one of the richest sites in biological diversity of the world. Deforestation, forest fragmentation and degradation are considered as serious problems in this region. Loss of tropical forests may have long term effects including change in regional climate especially rainfall pattern, biological productivity, acceleration of soil erosion, disruption of watershed stability, and increase in atmospheric temperature as well as further impacts on global climate dynamics.

Shifting cultivation, permanent agriculture and human settlement have reduced the natural forest to a series of fragmented forests of varying size in the highland watershed areas of northern Thailand. Some patches are still abundant while the others may be degrading through tree cutting and selective uses of non-wood products by local people. It may lead to the extinction of locally adapted populations as well as a reduction in the size of remnant populations. The decline of population size leads to genetic isolation of once contiguous populations and may result in an increase in the level of inbreeding (Murawski and Hamrick, 1992). Deforestation and forest fragmentation threat to genetic diversity by giving an impact to gene exchange depends upon pollen and seed dispersal (Bawa *et al.*, 1985; Bawa, 1993).

On the other hand, the fragmented forests remained in the highland watershed may be useful for the reforestation project. Forest plantation plays the key role in harmonizing long-term forest ecosystem restoration goals. Adjacent fragmented forests can disperse fruits or seeds of many species for succession in plantations to increase biodiversity enrichment, and thus the plantations can be developed to be a natural forest. Normally, seeds can be dispersed by gravity, and seeds of some plant species can increase distance from the sources by wind, water, animal and explosions and others (Schmidt, 2000). Seeds dispersal mechanisms should have a direct impact on the genetic structure of populations (Hamrick *et al.*, 1993). The morphology of fruits and seeds often reflects the mode of dispersal (Schmidt, 2000). Heavy seeds are the features of tree species in many families such as Proteaceae, Fagaceae, Lauraceae, etc., and influence on their spatial distribution and abundance (Sri-ngernyuang *et al.*, 2007). However, most of tree species in the tropics are dispersed by animals rather than wind, water or other forms of dispersal (Wunderle, 1997).

The purpose of this study is to investigate plant species diversity in fragmented lower montane (LMF) forests which may have the potential roles on natural succession in plantation forests as well as opened areas after shifting cultivation in highland watershed of northern Thailand.

3.2 Materials and Methods

3.2.1 Vegetation Sampling

A sampling plot (quadrat) of $40 \times 40 \text{ m}^2$ was used for vegetation survey in each of fifteen fragmented forests. All plots were located using GPS and topographic map. Each plot was divided into 16, $10 \times 10 \text{ m}^2$ subplots, and all woody trees and climbers with $\geq 1.5 \text{ m}$ height were measured for gbh (stem girth at breast height, 1.3 m above ground), and tree height.

Two small plots of $5 \times 5 \text{ m}^2$ in size were placed at the center of the big plot to investigate ground-covered species and natural regeneration by identifying species names and counting number of seedlings.

3.2.2 Calculation of Ecological Parameters

The data were calculated for ecological parameters of tree species and plant communities: frequency, density, dominance, important value index (IVI), similarity and species diversity index (Krebs, 1985), as well as the relation, resemblance function and clustering.

(1) Plant Frequency

$$\text{Frequency} = \frac{\text{Number of occupied quadrats}}{\text{Number of all quadrats}} \times 100$$

$$\text{Relative frequency} = \frac{\text{Frequency of species } i}{\text{Sum of frequency values of all species}} \times 100$$

(2) Plant Density

$$\begin{aligned}\text{Density} &= \frac{\text{Number of individuals of species } i}{\text{Number of all quadrats}} \text{ (trees/quadrat)} \\ \text{Relative density} &= \frac{\text{Number of individuals of species } i}{\text{Number of individuals of all species}} \times 100\end{aligned}$$

(3) Plant Dominance

The relative dominance of tree species is calculated from the stem basal area.

$$\text{Relative dominance} = \frac{\text{Stem basal area of species } i}{\text{Sum of stem basal area of all species}} \times 100$$

(4) Important Value Index (IVI)

The IVI is a composite index based on measures of relative frequency, relative density and relative dominance (Mueller-Dombois and Ellenberg, 1974). It is an integrated influence of a tree species in the forest. The value varies between 0 and 300. However, it can be expressed in term of relative IVI.

$$\begin{aligned}\text{IVI} &= \text{Relative frequency} + \text{Relative density} + \text{Relative dominance} \\ \text{Relative IVI} &= \frac{\text{IVI of species } i}{\text{Sum of IVI of all species}} \times 100\end{aligned}$$

(5) Index of Species Diversity

The Shannon-Wiener index (SWI) relates the proportional weight of the number of individuals per species to the total sample belonging to all species (Kreb, 1985).

$$H = - \sum_{i=1}^S (p_i)(\log_2 p_i)$$

Where H = index of species diversity
 S = total number of species
 p_i = proportion of individuals of species i to total individuals of all species

(6) Forest Condition Index (FCI)

The index of species diversity in a forest does not imply to forest condition since it is calculated from the sum of relative number of all tree species in the sampling plots without classification of each tree species into saplings, immature, mature and old trees. Different types of primary forests usually have different species diversity. Some forest types may be classified as species-poor ecosystems whereas the others are the species-rich ecosystems. Within the same forest type, species diversity is changed with different stages of plant succession and disturbance. The forests at the early and middle stages may have the higher diversity than that in the climax stage. The forest conditions as good, intermediate or poor are considered from the

relative number of small, intermediate and big trees. The poor forest usually has mainly small trees, whereas those forests of the more good conditions will have increasing the relative number of intermediate-size and big trees.

Assessment of forest communities as good, intermediate and poor conditions was carried out using the number of individual trees with different stem-girth classes. The intermediate-size and big trees were significant to the value of forest condition index than smaller trees. The stem-girth classes were divided into 0-25, 25-50, 50-75, 75-100,, respectively, and the FCI was calculated for each class. The index of forest condition is the sum value of the number of individual trees for all classes. The importance of n_1 was 1/100, increased to 1/10 for n_2 and to 1.0 for n_3 to n_n .

$$\text{FCI} = \Sigma n_1 \cdot 10^{-2} + n_2 \cdot 10^{-1} + (n_3 + n_4 + n_5 + \dots + n_n) \cdot 1$$

Where FCI = index of forest conditions
 n_1 = number of individual trees with $\text{gbh} < 25 \text{ cm}$
 n_2 = number of individual trees with $\text{gbh} 25\text{-}50 \text{ cm}$
 n_3 = number of individual trees with $\text{gbh} 50\text{-}75 \text{ cm}$
 n_4 = number of individual trees with $\text{gbh} 75\text{-}100 \text{ cm}$
 n_5 = number of individual trees with $\text{gbh} 100\text{-}125 \text{ cm}$
 n_n = number of individual trees with $\text{gbh} n \text{ cm}$

(7) Index of Similarity

The similarity index is arithmetic comparison of those values common to two groups with the total value of both groups (Bray and Curtis, 1957).

$$\text{Similarity} = [2w/(a+b)]100$$

Where, W = sum of the lowest value of IVI in both community a and b
 a = sum of IVI in community a
 b = sum of IVI in community b

(8) Forest Regeneration

The number of seedlings of various tree species and ground-covered species in each fragmented forest were counted in the two small plots ($5 \times 5 \text{ m}^2$) which were placed at the center of the big plot to identify forest regeneration and number of ground-covered species.

3.3 Results

3.3.1 Plant Community Analysis of Fragmented Forests

3.3.1.1 Species Composition, Diversity and Forest Conditions

(1) Species Richness and Composition

The total number of plant species existed in the forest is called species richness. In fifteen fragmented forests, totally 103 species in 82 genus and 44 families

were found (Table 3-1 and Table 3-2). Dominant tree species were mainly *P. kesiya*, *C. acuminatissima* and *S. wallichii*. Codominant tree species were *Q. brandisiana*, *C. diversifolia*, *L. elegans*, *Q. vestita*, *T. gymnanthera*, *H. nilagirica*, *E. spicata*, etc. The small trees included mainly *T. rufescens*, *W. tinctoria*, and *V. sprengelii*. Many rare species in the forests were observed such as *M. henryi*, *S. albiflorum*, *S. cumini*, *T. chebula*, *C. armata*, *R. ignea*, *B. alnoides*, *A. gomezianus*, *C. iners*, etc. Some are true rare species and the others are usually existed in more abundance in forests of lower areas. The dominant families were Fagaceae (13 species), Leguminosae (8), Lauraceae (8), Euphorbiaceae (7), Rubiaceae (6), and Theaceae (6).

The species richness is typically high in LMF. Khamyong and Seramethakun (1998) reported that the same forest type at Mt. Doi Suthep in area of 1,200-1,300 m altitude consisted of 72 species (54 genus and 34 families), and it was increased to be 188 species (124 genus and 57 families) as the sampling area was expanded between 800-1,500 m (Khamyong, 2009). Loarpansakul (2000) found that the forest at the Queen Sirikit botanic garden consisted of 97 tree species (in 68 genus and 42 families), and it was high as 184 tree species (129 genus and 61 families) for the fragmented forests in Pang Ma Pha district, Mae Hong Son province (Seanchanthong, 2005). The species richness of montane forest at Mt. Doi Inthanon was declined with higher altitude by lower air temperature and cloud covering nearly throughout a year. It was low as 47 species in upper montane (UMF) forest at Mt. Doi Inthanon summit (Khamyong *et al.*, 2004).

(2) Species Diversity

Species diversity index in the whole fragmented forests by Shannon-Wiener Index (SWI) was calculated as 5.28 (Table 3-3), and varied among the fragmented forests with a range of 3.01-4.65. The patch sizes of fragmented forests were varied from small to big ones, and human disturbance through tree cutting was different among the patches. These indicated to some degradation of fragmented forests, and thus the SWI values were variable. The SWI of the whole fragmented forests was nearly the same with the lower montane forest at Doi Suthep-Pui National Park, 5.0-5.1 (Vanapraser, 1985), and implied to the high species diversity of original forest of these fragmented forests.

The SWI value is usually high in this forest. Khamyong and Seramethakun (1998) reported that the forest at Mt. Doi Suthep in area of 1,200-1,300 m altitude had the value of 4.5, and it was increased to be 6.1 as the sampling area was expanded (Khamyong, 2009). Laorpansakul (2000) found that SWI of the forest at the Queen Sirikit botanic garden was 5.67, and it was higher as 6.05 for the fragmented forests in Pang Ma Pha district, Mae Hong Son province (Seanchanthong, 2005). However, the SWI value of the upper montane forest at Mt. Doi Inthanon was lower as 4.26 (Khamyong *et al.*, 2004).

(3) Forest Condition Index (FCI)

The indexes of forest conditions were different among fifteen fragmented forests, and varied from 31.39 to 69.42. The value of 50.16 was calculated for the whole fragmented forests (Table 3-4). These implied to the different conditions of fragmented forests caused by human disturbance through selective tree cutting. For the pine-montane forest in other areas, Seeloy-ounkeaw (2011) found that two community forests including utilization and conservation forests at Nong Tao villages, Mae Wang district, Chiang Mai province, had indexes of forest conditions of 50.16 and 54.45, respectively. The forest condition and ecological features in this conservation forest was good compared to utilization forest. Therefore, the FCI values below 54.45 in some fragmented forests implied to the degraded forest.

(4) Growths and Size Class Distribution

The number of tree individuals of different height classes and stem-girth classes in fragmented forests were presented in Table 3-5 to Table 3-8.

The relationship between diameter at breast height (dbh) and tree height (H) showed in semi-log curve (Figure 3-1), which was approximated by the relation,

$$y = 0.4079x + 3.1174 \quad (R^2 = 0.7591)$$

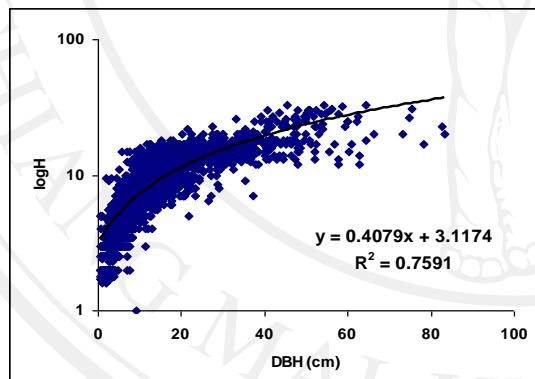

Figure 3-1 The relation between dbh and tree height in fragmented forests

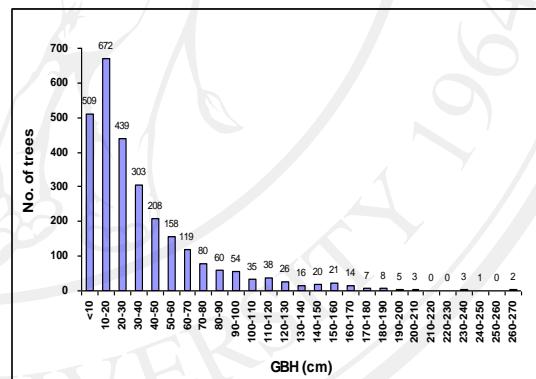

Figure 3-2 The size class distribution of gbh in fragmented forests

Size-class distribution can be used as indicators of changes in population structure and species composition (Newbery and Gartlan, 1996). Distribution curves that drop exponentially with increasing dbh (reverse-J-shaped) are characteristics of species with continuous regeneration. Most species in fragmented forests followed this pattern of distribution with plenty of individuals in the small size classes that indicated a good regeneration potential (Figure 3-2). Three pioneer species, *T. rufescens*, *W. tinctoria*, and *V. sprengelii* had the relative high density. The common species, *P. kesiya* and *C. acuminatissima* occurred in most fragmented forests.

3.3.1.2 Variations of Plant Communities

(1) Species Richness

The number of tree species per plot in fifteen fragmented forests was shown in Table 3-9. The values varied between 16 and 42 species (13-35 genus and 10-24 families). The species richness in each plot was rather low since most fragmented forests were situated at the summit of mountainous areas where forest sites were relatively dry. There were no correlation between the species richness and altitude gradient. The species richness was higher in mesic areas between 1,345-1,586 m altitude.

(2) Species Diversity Index

The indexes of species diversity in fragmented forests calculated by the Shannon-Wiener Index (SWI) varied from 3.01 to 4.65 (Table 3-10), and the value of 5.28 for the whole fragmented forests. The SWI value in each fragmented forest varied from low to intermediate. However, it was high for the whole fragmented forests. This implied to the high species diversity of the original montane forest in this watershed area.

(3) Tree Density

Tree densities were greatly different among fragmented forests, 556-1,769 individuals/plot. The tree densities were low in areas of 1,230-1,260 m altitude, and high between 1,300-1,560 m. It is found that some fragmented forests consisted of mainly intermediate-size and big trees whereas densely small trees were existed in the others. The human disturbance through selective tree cutting resulted in the big canopy gaps in some fragmented forests. This stimulated the natural regeneration, and many saplings were grown densely in the gaps. Thus, tree densities were higher in the disturbed forests.

(4) Stem Basal Area

The total stem basal area of all tree species in fragmented forests varied between 17.46-36.58 m²/ha. This parameter is implied to forest production according to stem size and number of trees, and forest condition. Since the fragmented forests had different forest conditions, from poor to good, the values were therefore greatly different.

Figure 3-3 Over views pictures of fragmented forests

(5) Similarity

The similarity percentages of plant communities among fragmented forests were varied within a wide range, 2-78% (Figure 3-5). These indicated that some fragmented forests were not similar to the others. The distance between fragmented forests and different altitude ranges were important factors. The nearest distance between the two fragmented forests with the same altitude showed the high similarity.

Altitude (m)	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

Figure 3-4 Similarity percentages of plant communities among fragmented forests

(6) Spatial Distribution

The distribution and population abundance along altitude gradient of tree species in fragmented forests were different: *P. kesiya* and *C. acuminatissima*; 1,200-1,500 m msl, *Q. brandisiana* and *A. fragrans*; 1,200-1,300 m, *L. elegans*, *T. gymnanthera* and *C. purpurea*; 1,300-1,400 m, and *C. diversifolia*, *T. gymnanthera*, *H. nilagirica*, *S. wallichii*, *Q. vestita* and *E. nitida*; 1,400-1,500 m (Figure 3-6). Altitude is the complex gradient that is highly correlated with temperature, light intensity, rainfall and condensation, and soil parameters (Grubb, 1977; Vetaas, 1997; Givnish, 1999; Hansen, 2001; Ashton, 2003). The altitude was the most important environmental variable explaining species composition and vegetation structure of montane forest (Khamyong *et al.*, 2004). Different tree species in the montane forest can adapt to variable environmental conditions along altitude gradient particularly air temperature. Therefore, the tree species in this forest may be identified as subtropical and temperate species.

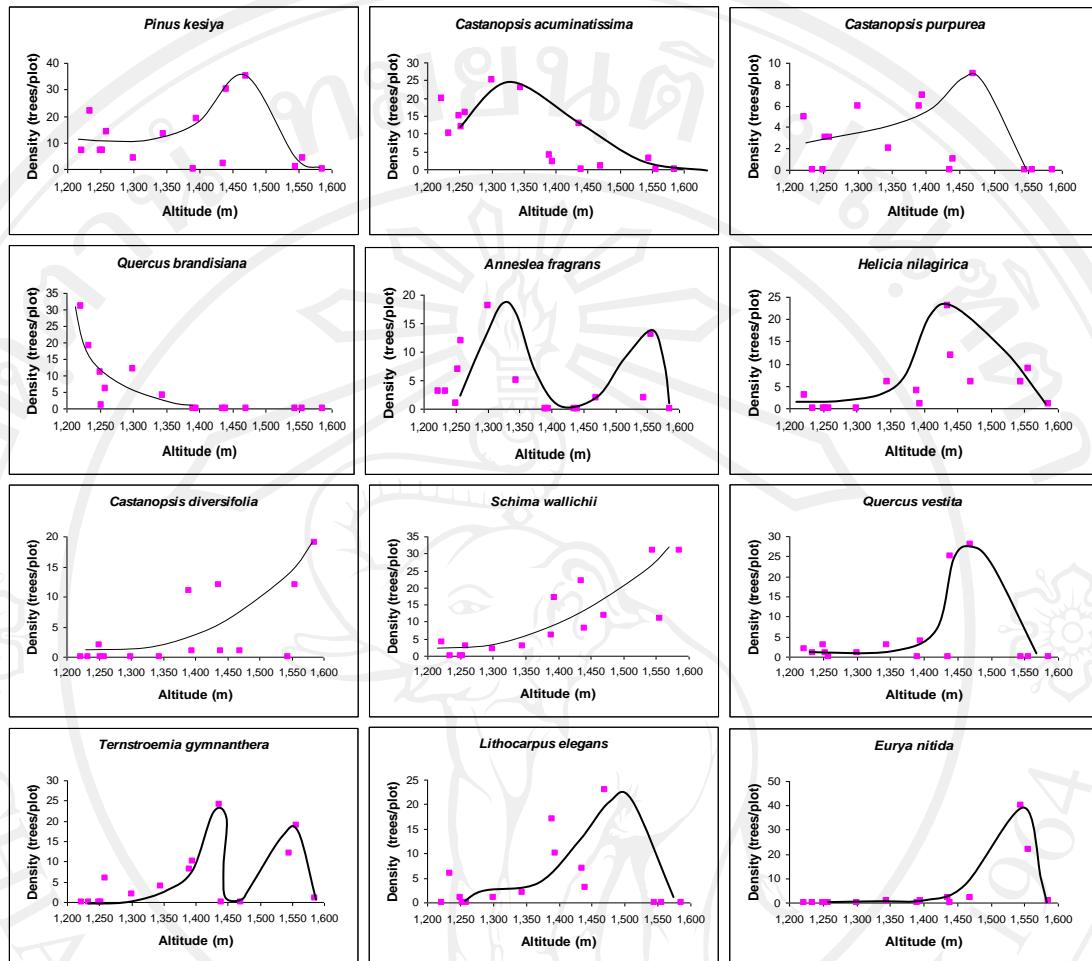

Figure 3-5 Spatial distribution of dominant tree species in fragmented forests located on different altitudes

3.3.1.3 Quantitative Characteristics of Tree Species

(1) Tree Frequency

There were five tree species having the frequency values over than 80% in fifteen fragmented forests including *W. tinctoria*, *P. kesiya*, *G. sphaerogynum*, *C. acuminatissima* and *S. wallichii*. These trees existed in most fragmented forests. The tree species having the lower frequency (60-80%) were *P. emblica*, *T. rufescens*, *V. sprengelii*, *H. nilagiriga*, *A. fragrans*, *C. stellatum*, *T. gymnanthera*, *L. elegans*, *E. spicata*, *C. purpurea*, *Q. vestita*, *D. cultrata*, *S. albescens* and *S. benzoides*.

(2) Tree Density

The average tree density in the whole fragmented forests was 1,166 trees/ha. The shrubby tree, *T. rufescens* had the highest density (116 trees/ha), and followed by *W. tinctoria* (91), *V. sprengelii* (86), *P. kesiya* (69), *S. wallichii* (63) and *C. acuminatissima* (60).

(3) Tree Dominance

The dominance was calculated on the basis of the stem basal area. *P. kesiya* had the highest relative dominance (24.10% of all species), and followed by *C. acuminatissima* (14.12%), *S. wallichii* (7.14%), *C. diversifolia* (5.84%), *Q. brandisiana* (5.28%), *T. rufescens* (4.10%) and *C. purpurea* (3.46%).

(4) Importance Value Index (IVI)

The IVI value combines relative frequency, relative density and relative dominance into a measure that can be used to indicate the ecological influence of each species in the forest. *P. kesiya* had the highest value (11.02% of all species), and followed by *C. acuminatissima*, *T. rufescens*, *S. wallichii*, *W. tinctoria*, *V. sprengelii*, *Q. brandisiana*, *C. diversifolia*, *T. gymnanthera* and *H. nilagirica*. These ten tree species were accounted for 49.06% of the total IVI.

These fragmented forests were remained at the ridge or upper slopes of the high mountains where the sites were relatively dried during summer. The forest conditions were favorable for the pine (*P. kesiya*) and some broad-leaved tree species. Mycorrhizal fungi usually associate with the roots of these tree species and help for nutrient uptake and moisture absorption.

(5) Similarity of Plant Communities

Deforestation often produces landscape-level changes in forest characteristics and structure, including area, distribution and forest habitat types. Changes in landscape pattern through fragmentation or aggregation of natural habitats can alter patterns of abundance for single species and entire communities (Quinn and Harrison, 1988). Some patches are still abundant while the others may be degraded through tree cutting and selective uses of non-wood products by local people. A decrease in the size and number of natural habitat patches increased the loss of species diversity whereas a decline in connectivity between habitat patches can negatively affect regional species persistence (Fahring and Merriam, 1985).

By using cluster analysis to find homogeneous groups of variables in fifteen fragmented forests. The dendrogram showed the four-cluster solution (Figure 3-8 and Table 3-11).

Cluster 1 composed of FF1 and FF2: the altitude was quite high, ranging from 1,440-1,470 m. Species richness was 16-21 species, and SWI was 3.01-3.37 which both values were lower than other fragmented forests because the areas were near the road so they had some disturbances by humans through tree cutting. The dominant species were *P. kesiya*, *W. tinctoria*, *T. rufescens*, *L. elegans*, *S. wallichii* and *Q. vestita*.

Cluster 2 composed of FF3 and FF11: the altitude was intermediate in range from 1,390-1,395 m. Species richness was 40-42 species, and SWI was 4.15-4.65. These fragmented forests were still abundant. The dominant species were *P. kesiya*, *W. tinctoria*, *C. purpurea*, *S. wallichii*, *P. emblica*, *L. fenestratus*, *L. elegans*, *C. acuminatissima*, *C. diversifolia* and *D. cultrata*.

Cluster 3 composed of FF4, FF5, FF6, FF7, FF8, FF9 and FF10: the altitude was quite low in range from 1,222-1,345 m. Species richness was 16-34 species, and

SWI was 3.45-4.38. They were the disturbances in some fragmented forests through tree cutting. The dominant species were *P. kesiya*, *V. sprengelii*, *C. acuminatissima*, *Q. brandisiana*, *A. fragrans*, *T. rufescens* and *C. stellatum*.

Cluster 4 composed of FF12, FF13, FF14 and FF15: the altitude was quite high in range from 1,436-1,586 m. Species richness was 32-37 species, and SWI was 3.88-4.51. These fragmented forests were still abundant. Some small disturbance may be happened in these fragmented forests. The dominant species were *C. diversifolia*, *T. gymnanthera*, *W. tinctoria*, *H. nilagirica*, *A. fragrans*, *E. nitida*, *E. spicata*, *P. kesiya* and *C. acuminatissima*.

Fragmented forests in the same cluster had the nearest of distance with the same altitude. However, there were some variables of species richness, density, basal areas and species diversity among fragmented forests in the same cluster because of human disturbance through tree cutting.

3.3.1.4 Natural Regeneration and Ground-covered Species

The total number of seedling and ground-covered species existed in the whole fragment forests were 96 species which could be separated to 74 species of tree, 13 species of herb, 8 species of climber and one species of fern. The average number of seedling and ground-covered species was 780 individuals/ha, and varied within a wide range among fragmented forests, 231-1,856 individuals/ha (Table 3-13). They were very few in the good forests and very dense in canopy gaps of degraded forests. The common seedlings of woody species were *Micromelum minutum*, *Phoebe cathia*, *P. paniculata*, *Dillenia aurea*, *Terminalia chebula* and *Euodia roxburghiana*. The herb species were *Orthosiphon aristatus*, *Asparagus filicinus*, *Chromolaena odoratum* and *Ageratina adenophora*. The regeneration of *Q. brandisiana* was better than other oaks, but usually on the dry site.

The natural regeneration is considerably poor in most fragmented forests, and mainly plant species adapted to the dry site were dominated on the forest floor according to moisture limitation and forest fire during summer. Moreover, nutritional differences in forest soils are important in influencing the species composition of seedlings regeneration (Brandani, *et al.*, 1988). The regeneration of climax species in such sites depended upon existing seedlings. The climax species do not germinate or establish well in the large gaps (Howe *et al.*, 1985; Tomboc and Basada, 1978; Turner, 1990), and are notoriously poorly dispersed (Burgess, 1970), whereas pioneer species show their highest levels of germination in large gaps and seedlings may grow very rapidly in full light (Raich and Gong, 1990; Kennedy and Swaine, 1992).

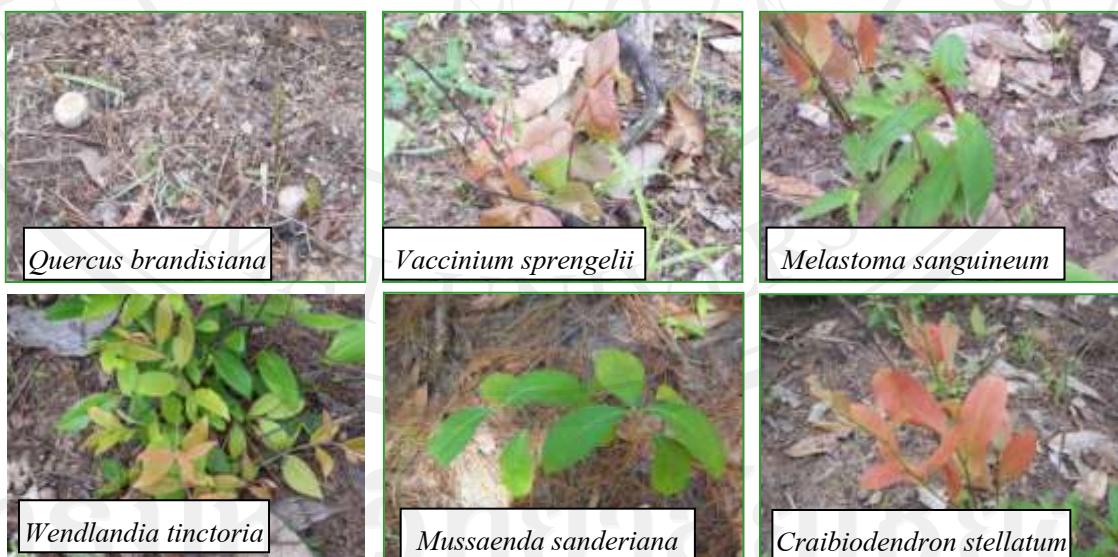

Figure 3-8 Some seedlings and ground-covered species in fragmented forests

3.3.2 Potential Roles of Fragmented Forests on Succession in Pine Plantations

The fragmented montane forests nearby the pine plantations in highland watershed have important roles on natural succession in plantations as the sources of seeds/fruits. The natural succession begins as seeds/fruits of various species are dispersal into the plantations, germination and establishing seedlings. The saplings and small trees may grow slowly beneath pine canopy for many years until they grow up to be mature trees. Some individuals of pine may be died during the sucessional stages, and finally most areas will be covered by broad-leaved tree species and some pine trees may be remained paritcularly on the ridge areas.

3.3.2.1 Seed/Fruit Characteristics and Dispersal Potential

The seed/fruit characteristics of 103 tree species and their possible seed dispersal agents were identified (Table 3-1), and used to describe about the potential roles of tree species on plant succession in adjacent *P. kesiya* plantations of Boakaew Watershed Management Station.

Thirty-five tree species in the fragmented forests had seed dispersal by wind such as *P. kesiya*, *S. wallichii*, *B. alnoides*, *D. serrulata*, *S. neuranthum*, *C. stellatum*, *E. serrata*, *E. spicata*, *A. chinensis*, *T. rufescens*, *R. javanica*, etc. The seeds of 49 tree species were identified as animal dispersal such as those in the families of Fagaceae, Lauraceae, Euphorbiaceae, Burseraceae, Proteaceae, etc. The explosion dispersal was found for 12 species such as *M. malabathricum*, *W. tinctoria*, *C. arborea*, *V. pinnata*, *M. henryi* and those in the family of Leguminosae. Some heavy-seed tree species dispersed the seeds surrounding the mother trees including *P. diospyricarpa*, *A. fragrans*, *T. cochinchinensis*, *S. arboreum*, *E. subcoriacea*, *B. gammieana* and *S. albescens*.

Wind dispersal is prevalent in open forests and among pioneers, but also some climax rain forest species whereas animal dispersal occurs in all forest types but is most prevalent in closed and stable forests (Schmidt, 2000). Sri-ngernyuang, *et al.* (2007) found that seed dispersal distance of Lauraceae including two pioneer species (*Litsea cubeba* and *Lindera metcalfiana*) and two shade-tolerant species (*Cinnamomum soegengii* and *Cryptocarya densiflora*) was short (less than 12 m), and the density of seed dispersal had a mode at 0-2 m from mother tree caused by heavy fresh seeds. Each seed contains the potential for becoming a full grown tree, but in nature most seeds succumb from germination failure (Schmidt, 2000). Dispersers of large fruited species are often the larger bodied wildlife, species themselves most often at risk from forest fragmentation and have tended to lack of regeneration (Tucker and Murphy, 1997; Parrotta *et al.*, 1997; Corlett and Hau, 2000). Small mammals and forest birds are unlikely to move across inhospitable habitats among forest fragments (Grant, 1971). Remaining fragments of old-growth forest may be critical for some species and should be protected and rehabilitated (Vanclay, 1992).

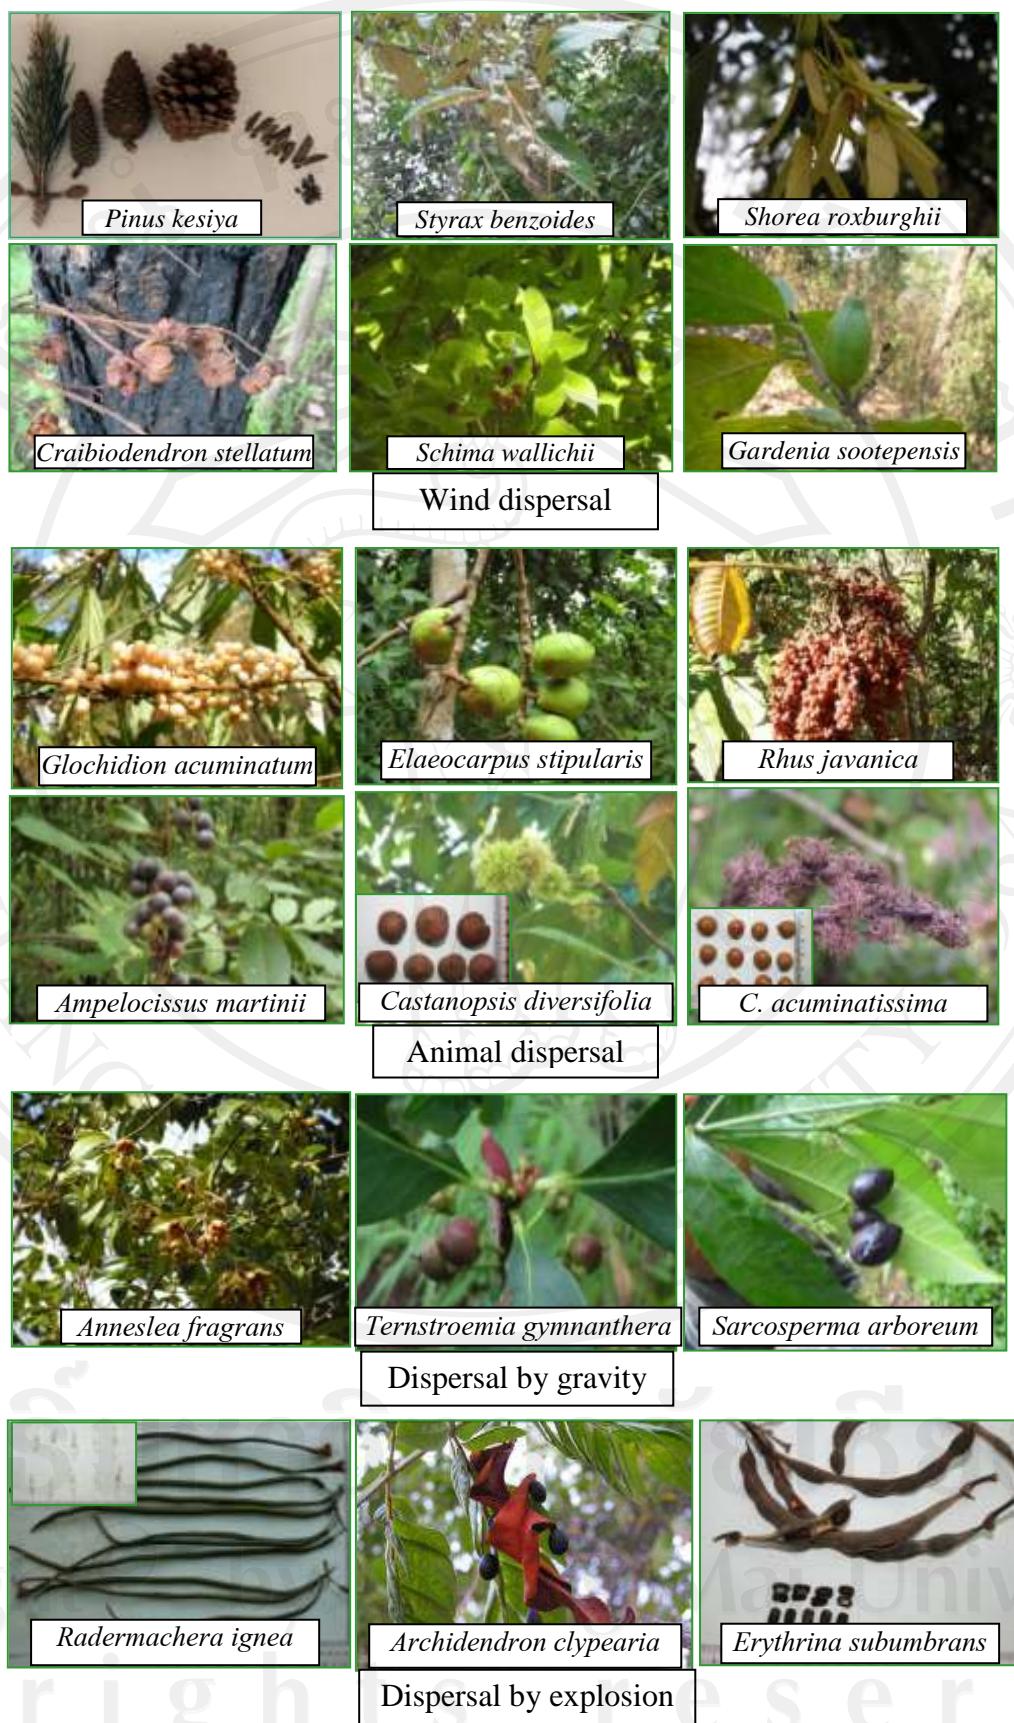

Figure 3-9 Modes of fruits/seeds dispersal

3.3.2.2 Succession Tree Species in Pine Plantations

The tree species in fragmented forests were important for natural succession in pine plantations on highland watershed areas. It is found that there were 87 tree species common to both fragmented forests and pine plantations (Table 3-14). The common tree species in both sites were *S. wallichii*, *W. tinctoria*, *G. acuminatum*, *P. emblica*, *G. sphaerogenum*, *C. diversifolia*, *P. kesiya*, *C. purpurea*, *T. rufescens*, etc. The numbers of tree species (16 species) were found in fragmented forests which were the rare species in these areas such as *Artocarpus gomezianus*, *C. armata*, *Combretum punctatum*, *Radermachera ignea*, *Schefflera bengalensis*. The number of 111 species were found in pine plantations such as *Melastoma sanguineum*, *Dalbergia assamica*, *Mallotus paniculatus*, *Memecylon celastrinum*, *Litsea cubeba*, *Blumea balsamifera*, *Elaeocarpus sphaericus*, *Neolitsea zeylanica*, *Gluta obovata*, etc.

Table 3-14 Species richness among fragmented forest and pine plantations

Type	No. of species		
	FF + PP	FF	PP
Tree species	87	16	111
Ground-covered species	76	20	111

Note: FF = fragmented forests, PP = pine plantations

3.4 Discussion

The natural process of forest succession can take place on disturbed forest and opened land after forest clearing. In disturbed and degraded forests, protection and maintainance of existing trees are a technologically simple and cost-effective by weeding, mulching and application of fertilizer. These will accelerate tree growths and natural regeneration. The more rapid restoration usually requires by planting of fast growing tree species which consist of pioneer and local tree species. Pioneer species can grow rapidly and forming forest canopy in order to change microclimate near ground level, whereas native trees species can enrich biodiversity. This will be led to the development of more intensive systems of forest restoration. However, development and design of appropriate management options to assist this process are important.

As the succession begins, the pioneer colonization of annual plant species which had short life spans (one growing season) occurred in the gaps. The plants which had the high densities included *Curcuma sessilis*, *Ageratina adenophora* and *Amorphophallus sp.*, whereas those of woody species were *Vaccinium sprengelii*, *Quercus brandisiana* and *Glochidion hirsutum*. The tree species which had light seed and produced a lot of seeds could establish well in full sunlight such as *V. sprengelii*, *Tristania rufescens*, *Craibiodendron stellatum*, *Leea guineensis*, *Wendlandia tinctoria*, *Rhus javanica*, *P. kesiya*, etc. The oak species, *Q. brandisiana* had the good succession in some fragmented forests of dry site whereas the other oaks (Fagaceae) had the poor succession.

In the early stage of forest succession in pine plantations, fast growing native pioneer species are important for improving microenvironment favorable for other new native tree species. The density of planted pine might be declined during the successional stages, whereas the overall tree density had increased. In all age class plantations, the pine trees were still the most dominant, while the succession tree species developed slowly to form dominant trees in the future stages. The forest structure of forest plantations will be changed to the climax montane forest. In the montane forest, most dominant trees are oaks whereas understory tree species may compose of diversified broad-leaved tree species. Pine trees will be remained in the forest only in the ridge areas as dominant trees, and xeric oaks as co-dominant trees. Therefore, the recovery process of forest plantations to be the climax montane forest may needs a long period of times, many decades or hundred years.

Many sylvicultural practices usually apply to manage forest plantations to improve productivity per unit area such as weeding, thinning, making fire lines, etc. However, reforestation by pine plantation was terminated for many years according to the national policy. Planting of some pioneer species and native tree species in the deteriorated forest is now practiced to recover the watershed forest. Selection of these tree species requires knowledge about their spatial distribution along altitude gradient. As the results, many tree species were found in fragmented forests with different altitude ranges: *P. kesiya* and *C. acuminatissima*; 1,200-1,500 m msl, *Q. brandisiana* and *A. fragrans*; 1,200-1,300 m, *L. elegans*, *T. gymnanthera* and *C. purpurea*; 1,300-1,400 m, and *C. diversifolia*, *T. gymnanthera*, *H. nilagirica*, *S. wallichii*, *Q. vestita* and *E. nitida*; 1,400-1,500 m.

The similarity of plant communities in fragmented forests which was classified by cluster analysis showed the results that cluster 2 (FF3 and FF11) and cluster 4 (FF12, FF13, FF14 and FF15) were abundant and relatively high species diversity, whereas cluster 1 (FF1 and FF2) and cluster 4 (FF4, FF5, FF6, FF7, FF8, FF9 and FF10) had some disturbances through tree cutting. It is important to preserve and has enrichment planting in these fragmented forests as seed/fruit sources for natural succession in shifting cultivated areas and adjacent plantations.
